INTRODUCTION

The following document is a final report for Grant Number DAAG29-79-G-0021 funded by the U.S. Army Research Office. This project was started 1 January 1979 and had a duration of two years.

In general, the project was 1) to develop a mathematical model describing heat transfer and temperature characteristics in ceramic coated engine components, 2) measure operational temperatures for such parts with various coating thickness, and 3) continue a previous endurance test of ceramic parts.

THEORETICAL BACKGROUND

PURPOSE

Since the time of Rudolph Diesel, engineers have been trying to develop engines that waste less energy, and thereby develop more power with a given quantity of fuel. It is widely accepted that heat transferred to the cooling system of an engine represents wasted energy. On the other hand, the only practical way known to control engine temperatures is to provide such cooling. In reciprocating engines, the design of pistons and valves has always required careful consideration of temperature as related to component strength and to lubrication. But the cooling necessary to keep these components from overheating not only reduces engine power production, but consumes power to drive the cooling mechanism.

It was recognized by the author that an insulating surface on combustion chamber surfaces offered an approach to the cooling problem by reducing heat transfer to the cooling system and, at the same time, provided lower temperatures of metallic components. Lower metallic temperatures allow redesigning of components for less weight and lower frictional drag.

From a design standpoint, therefore, lower piston temperatures enable lower piston weight, which leads to reduced inertia loadings thus allowing smaller and lighter components such as crankshaft bearings,

connecting rods, and crankcase structure. The lower temperatures also allow a new freedom in selecting lubricating oils that can reduce viscous drag and windage losses within the crankcase.

A second significant benefit that may result from ceramic coatings is the reduction of the failure rate in valves and pistons, and therefore an increase in engine reliability. While replacement costs for individual engine parts are not unreasonable, the time of failure and the labor required are often critical factors in vulnerable situations.

Engine failure is particularly critical in military applications. Often military engines are destroyed by a combination of operational factors in or near a combat zone. For example, it is not uncommon for the operator to refuel with any available fuel and then operate the vehicle at peak power for extended time intervals. Either a spark ignition (S-I) or a compression ignition (C-I) engine operated in this mode will develop severe knock. Knock, in turn, dramatically increases convection boundary layer heat transfer which may raise valve and piston temperature to a point of failure.

Figure 1, following, is a photograph illustrating a diesel exhaust valve failure caused by excessive thermal stress (hoop stress failure). A more common failure occurs when the valve head separates from the stem ("valve swallowing"), after high temperature stress and erosion. This second failure mode usually occurs at high power and high rpm conditions resulting in substantial, if not complete, engine destruction.

Two examples of piston damage resulting from high temperature operation are shown in figures 2 and 3. Both are caused by knock induced heat transfer. The second, however, was aggravated by preignition at the spark plug center electrode.

Insulated coatings are expected not only to economically eliminate all of the above types of engine failure, but also, to increase engine efficiency and reduce overall engine weight.

Based on the information above, it appears that one small breakthrough in controlling heat transfer offers the opportunity for major engine improvement. For these reasons, it is highly desirable to gain a better

Figure 1: Valve Failure

Figure 2: Piston Failure Knock

Figure 3: Piston Failure Preignition

understanding of how heat is transferred in ceramic coated internal combustion engine parts.

PREVIOUS WORK

Shortly after the principal investigator realized the possible benefits of insulated combustion chamber surfaces, he wrote a mathematical model to investigate coated engine performance. The model did predict both increased efficiency and lower component temperatures. Following analysis of the model, he participated in two engine test programs involving coated parts.

The first engine test program was a multicylinder test at the Johnson Space Center in Houston. The major outcome of this test was proof that plasma sprayed ceramic coatings could endure the torturous environment of an engine combustion chamber for extensive periods of time without significant deterioration.

The second test program was a U.S. Army funded study at Oklahoma State University which investigated engine performance characteristics. Both spark ignition (S-I) and compression ignition (C-I) performance were investigated at various compression and equivalence ratios. These tests incorporate a thin coating (0.025") of yttrium stabilized zirconium oxide on the piston, valves, and cylinder head surfaces of a Cooperative Fuel Research (CFR) engine. In addition, tests were undertaken to investigate how various catalysts applied to these coatings will affect combustion. The details of this project are found in the final report, project No. P-14099-E entitled "Improved Engine Performance Through Heat Transfer Control", available by contacting the U.S. Army Research Office, Research Triangle, North Carolina.

CERAMIC COATINGS

Several ceramic substances have been developed in the last few years that exhibit excellent insulating properties. These substances can be sprayed on metal surfaces by flame or plasma methods and also can be applied by a device known as a detonation gun. Some properties of various

coatings and metals follow in table 1.

To reduce heat transfer in an engine cylinder, two physical coating properties are of prime importance. First, the material must adhere to the metallic subsurface without any significant interface stress over a wide range of temperature. This necessitates that the coefficient of thermal expansion of the coating should be of the same order of magnitude as the base structure. Second, it should have as low a thermal conductivity as possible in order to effectively control heat transfer. Properties of lesser importance are specific heat, compressive strength, and adherence. Of all the coating materials investigated, yttrium stabilized zirconium oxide best fits the requirements for engine combustion chamber insulation.

Adherence of plasma and flame sprayed zirconium oxide to cast iron and aluminum surfaces is, however, in some cases not good, and coating separations will occur if proper techniques are not observed. Metallic surfaces must be clean and free of oil prior to coating. In some cases, it may be necessary to preheat cast iron surfaces to expel residual oil from machining process. To promote good bonding, it is suggested that metallic surfaces be grit blasted and given a flash coat of nickel aluminate before application of the zirconium oxide coating.

PROJECT SCOPE

The preceding section has outlined the historical use of ceramic coatings to improve engine performance and to make engines more tolerant of low grade fuel. This project was undertaken to establish a data base to assist design engineers in the adoption of ceramic coatings.

To achieve this goal, a two year project was implemented to:

- 1) create a mathematical model that can predict piston and exhaust valve heat transfer as a function of engine design parameters and coating characteristics,
- 2) establish operational temperature profiles for coated pistons and valves, and
- 3) an additional assignment for this project was to

continue an endurance test for ceramic coated engine parts. Prior to the start of this project an engine had undergone 1000 hours of operation simulating highway conditions. A second 1000 hours of operation was established as a third goal of this project.

THE MATHEMATICAL MODEL

GENERAL

Engine pistons and exhaust valves are three dimensional objects having configurations that can typically be portrayed by figures 4 and 5, respectively.

The piston and valve combustion chamber surfaces receive a cyclic heat input during each combustion, expansion and exhaust process. This heat flow depends primarily on the power loading of the engine and the combustion characteristics. These same surfaces are also subjected to a cyclic cooling during the intake and compression processes. The cooling tendency varies mainly with air-fuel ratio and engine power level.

Primary piston cooling is through the piston rings and heat transfer to lubricating oil, both being somewhat cyclic in nature.

Exhaust valve heat rejection occurs primarily to the valve seat and valve guide. Both of these sinks change characteristics with time and therefore are transient in nature.

While both the piston and exhaust valve are transient heat transfer devices, they may be treated as steady state for practical purposes. The insulating effect of a ceramic surface tends to isolate the core metal structure from temperature fluctuations, in other words, it is believed that the interior temperature of both such pistons and valves is controlled more by the constant temperature sink and the physical properties of the metal than by the cyclic heat load. This theory was verified in the laboratory; details and test data confirming this will be presented later.

As seen in figure 5, the exhaust valve is symmetrical and can, therefore, be treated as a two dimensional heat transfer body.

Figure 4: Typical Piston Configuration

Figure 5: Typical Valve Configuration

The piston is also basically symmetrical with the exception of the wrist pin boss. This boss, however, is typically located well below the ring area and, therefore, is usually considered to have little contribution to the overall piston heat transfer. Studies indicate that most heat transfer takes place in the upper ring area and on the top portion of oil cooled lower piston crown (1-7)* and, therefore, confirm that the wrist pin boss may be treated as an insignificant factor in heat transfer. This reasoning allows one to treat piston and valve heat transfer as a two dimensional, steady state problem.

If one first examines the general relationships for three dimensional heat transfer in an element as shown in figure 6, he can determine the heat transfer (8) in each of the three directions from

$$q_x = -KA \left(\frac{\partial T}{\partial x} \right) \quad (1)$$

where $A = dy dx$,

$$q_y = -KA \left(\frac{\partial T}{\partial y} \right) \quad (2)$$

where $A = dx dz$,

and

$$q_z = -KA \left(\frac{\partial T}{\partial z} \right) \quad (3)$$

where $A = dx dy$,

where T is temperature, K is thermal conductivity, and q is heat transfer. The three dimensional heat conduction equation for homogeneous materials without interior heat generation is:

*References are at the end of narrative.

Figure 6: Elemental Heat Transfer

$$\frac{\partial T}{\partial t} = K \left(\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2} \right) , \quad (4)$$

where t is time.

For steady state conditions $\frac{\partial T}{\partial t} = 0$ and equation 4 becomes

$$\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2} = 0. \quad (5)$$

The above is known as Laplace's Equation and is often written as $\Delta T = 0$. If Laplace's Equation is transformed to cylindrical coordinates by substituting $x = r \cos\theta$; $y = r \sin\theta$; and $z = z$; and if cylindrical symmetry is assumed

$$\left(\frac{\partial T}{\partial \theta} = 0 \right),$$

the equation reduces to:

$$\frac{\partial^2 T}{\partial r^2} + \frac{1}{r} \frac{\partial T}{\partial r} + \frac{\partial^2 T}{\partial z^2} = 0 . \quad (6)$$

Since symmetry is justified in this study, equation 6 becomes the governing equation for pistons and exhaust valves. Figure 7 illustrates this application for a piston.

To solve the heat transfer problem for such components, one must solve Laplace's Equation having certain boundary conditions known. A finite difference approach to this solution has been selected and will follow.

FINITE DIFFERENCE METHOD

Laplace's Equation has a unique solution for each set of boundary conditions specified. However, analytical solutions have been worked out only for problems with certain special geometries and boundary conditions. The following solution will be to overlay the cross section of the piston (and valve) with a grid of points (r, z) and to

Figure 7: Piston Cross Section

find the temperature at each point numerically. A typical grid is as follows in figure 8.

The numerical approach first approximates the partial derivatives at each point by using a finite difference or

$$\frac{\partial T}{\partial r}(r,z) \doteq \frac{1}{2h_1} [T(r+h_1,z) - T(r-h_1,z)] \quad (7)$$

$$\frac{\partial^2 T}{\partial r^2}(r,z) \doteq \frac{1}{h_1^2} [T(r+h_1,z) + T(r-h_1,z) - 2T(r,z)] \quad (8)$$

and

$$\frac{\partial^2 T}{\partial z^2}(r,z) \doteq \frac{1}{h_2^2} [T(r,z+h_2) + T(r,z-h_2) - 2T(r,z)] \quad (9)$$

where h_1 is the horizontal grid spacing and h_2 is the vertical grid spacing.

Equation 6 now becomes:

$$\begin{aligned} & \frac{1}{h_1^2} [T(r+h_1,z) + T(r-h_1,z) - 2T(r,z)] + \frac{1}{rh_1} [T(r+h_1,z) - T(r-h_1,z)] + \\ & \frac{1}{h_2^2} [T(r,z+h_2) + T(r,z-h_2) - 2T(r,z)] = 0. \end{aligned} \quad (10)$$

For the center line element ($r = 0$) a slightly different approximation is needed. As

$$r \rightarrow 0, \quad \frac{1}{r} \frac{\partial T}{\partial r} \rightarrow \frac{\partial^2 T}{\partial r^2}$$

so the governing equation becomes:

$$2 \frac{\partial^2 T}{\partial r^2} + \frac{\partial^2 T}{\partial z^2} = 0. \quad (11)$$

Figure 8: Piston Grid Network

The above can be simplified if $h_1 = h_2$ and the following substitutions are made:

$$T_{(r+h,z)} = T_{i+1,j}$$

$$T_{(r-h,z)} = T_{i-1,j}$$

$$T_{(r,z+h)} = T_{i,j+1}$$

The following finite difference equations exist for all points except where $r = 0$:

$$0 = -4 T_{i,j} + T_{i,j+1} + T_{i,j-1} + \left(1 - \frac{h}{2r}\right) T_{i-1,j} + \left(1 + \frac{h}{2r}\right) T_{i+1,j} \quad (12)$$

For center line points, ($r = 0$), the corresponding finite difference equation is:

$$0 = -6 T_{i,j} + 2T_{i-1,j} + 2T_{i+1,j} + T_{i,j+1} + T_{i,j-1} \quad (13)$$

which by symmetry yields:

$$0 = -6 T_{i,j} + 4 T_{i+1,j} + T_{i,j+1} + T_{i,j-1} \quad (14)$$

MODELING THE CERAMIC COATING

Special consideration must be given to the points where the ceramic coating meet the metallic piston (valve) surface. Linear equations for these points are obtained by assuming a one dimensional flow across the ceramic and using the heat equation:

$$q = -KA \frac{\partial T}{\partial z} . \quad (15)$$

This is illustrated in figure 9.

To obtain an equation involving T_1 , T_2 , and T_3 one can calculate the heat flowing through the interface area (A) both from the ceramic and the metal.

$$q = -K_c A \left(\frac{T_1 - T_2}{d} \right) \quad (16)$$

and

$$q = -K_m A \left(\frac{T_2 - T_3}{h_2} \right) \quad (17)$$

Equating these equations yields:

$$\frac{K_c A}{d} (T_1 - T_2) = \frac{K_m A}{h_2} (T_2 - T_3) \quad (18)$$

or

$$T_2 = \frac{h_2 K_c T_1 + d K_m T_3}{h_2 K_c + d K_m} \quad (19)$$

This gives a linear equation for each grid point of contact from the ceramic and the metal.

COMBINED SOLUTION

An equation now exists for the temperature at each interior point (r, z) and the surrounding grid points. The n -equations involving n -unknowns have been generated. These equations can be solved directly by Gaussian elimination or by an iterative process like the Gauss-Seidel method. In the Gauss-Seidel method the temperature at one point (r, z) is solved in terms of the temperatures at all surrounding grid points.

The result is a temperature distribution throughout the piston or valve.

Figure 9: Ceramic Metal Interface

DETERMINATION OF THERMAL CONDUCTIVITY

The thermal conductivity of each substance involved must be accurately known over a range of temperatures before any mathematical model can be completed. The temperature dependency of aluminum, steel, cast iron and other metals is well known and documented over a reasonable range. Plasma sprayed zirconium oxide, however, does not have a widely accepted conductivity at the temperatures involved by engine components.

Before completion of a mathematical model, therefore, it was necessary to determine such values. Samples of steel were machined to a standard sample size. Several of these were plasma sprayed with yttrium stabilized zirconium oxide using the same techniques as for engine parts. These samples, as well as uncoated specimens, were sent to the Thermo-physical Properties Research Laboratory at Purdue University for evaluation. The results of this analysis were incorporated in the following computer model and are presented as appendix 1.

THE COMPUTER PROGRAM

The preceding section has illustrated a mathematical method to describe the temperature at all interior points for engine parts that encounter two dimensional (r,z), steady state heat transfer.

A major portion of this effort was to incorporate these equations into a computer program that would give engineers a tool for designing engines that incorporate ceramic coated pistons and valves. The following section outlines the details of the resulting program.

Figure 10 details the step by step procedure to input component details into the program and to acquire the resulting temperature profiles and heat transfer.

To implement the program, a grid must be established similar to the one following in figure 11. The temperature at each solid dot is needed in the data.

The first data card contains the number of rows, the number of columns, the number of data sets, the conductivity of the coating, the conductivity of the metal, and the acceptable iteration limit. A data

Figure 10: Program Flow Chart

Figure No. 10: (continued)
Program Flow Chart

Figure No. 10: (continued)
Program Flow Chart

Figure 11: Piston Grid Points

set consists of the boundary temperatures for the test of a particular configuration. This information applies to all the data sets that follow. Each data set is composed of four sections. The first section is a single card which contains the label for the data set. The second section contains the temperatures along the outer edge. For each row there is one card which contains the edge temperature, and the dimensions to the point from the top and perimeter of the component by column number. The vertical dimension is recorded in inches of depth while the horizontal dimension is stated only by column number. The format for these cards is (F10.3, F9.3, I2). The temperature is recorded in degrees Fahrenheit (in agreement with the units on thermal conductivity) and the distance is recorded in inches.

The third section of the data set is composed of the surface temperatures and column spacing. For each column in the grid, a surface temperature and distance from the center of the piston valve is given. The format is (2F10.3). Again, the temperature is in degrees Fahrenheit and the radial location is recorded in inches.

The last section of the boundary data contains the temperatures on the bottom and interior wall (crankcase surface) for the piston and for the tulip on the valve. Each data card in this section contains a row, column, and temperature of a boundary point not covered in either section two or three.

A data card of this type with row = 20 and column = 20 is needed to signal the end of the data for each set. The format for these cards is (2I5,F10.3).

Note that the distance between rows 1 & 2 corresponds to the coating thickness. As written, this program solves for 9 rows and 9 columns. This quantity can be increased by changing the format and programming for the last data card of the fourth data section.

The output of this program contains a representation of the boundary values inputed into the program, a final temperature for each grid point, and the rate of heat flow vertically from the surface of the piston (or valve) in BTU/hr.

A card by card listing of the final version of the program follows:

(see next page)

A sample set of data cards used to test the program is listed below:

(see following pages)

These data cards produce an output as follows:

(see following pages, table 4-Program Output).

The following is a series of two profiles, each of which roughly outlines the geometry of the part being tested. The top profile tabulates inputted temperatures and the respective location of each point. The top outside points has values of $r = 1.63$ inches, $z = 0.00$ inches and $t = 280$ °F. Interior points are unknown at the time of data input and are therefore printed as zero.

The calculated heat flow through the top surface is written between the two profiles and in this sample case equals 366.7 BTU per hour.

The second (lower) profile displays the calculated temperatures at interior points as well as the input data from the top profile. In both profiles, the area shaded by the letter "U" represents the crankcase environment.

The program gives one the ability to calculate heat flow and the temperature and distribution for any coated engine part with two dimensional heat flow.

OPERATIONAL TEMPERATURES

GENERAL

To design engines incorporating ceramic coated parts, it is desirable not only to have a mathematical model that calculates heat flow and interior temperatures, but also one needs information about actual surface temperatures as they relate to engine operating conditions. In addition

MAJOR VARIABLES USED
 TEMP(I,J) - TEMPERATURE AT GRID POINT I, J.
 NRONS - NUMBER OF ROWS IN GRID.
 NCOLS - NUMBER OF COLUMNS IN GRID.
 NRUNS - NUMBER OF DATA SETS TO BE RUN.
 XKINSU - CONDUCTIVITY OF THE COATING.
 XKMETL - CONDUCTIVITY OF THE METAL.
 AVGTCL - ALLOWABLE AVERAGE TEMPERATURE CHANGE
 IN DEGREES F BETWEEN ITERATIONS.
 MAXTOL - ALLOWABLE TEMPERATURE CHANGE AT ANY
 GRID POINT PER ITERATION.
 TEDGE(I) - TEMPERATURE ON THE EDGE AT ROW I.
 ZDIST(I) - VERTICAL DISTANCE TO ROW I.
 RDIST(I) - DISTANCE FROM CENTER TO COLUMN I.
 DZ(I) - DISTANCE BETWEEN ROW I AND ROW I+1.
 DR(I) - DISTANCE BETWEEN COLUMNS I AND I+1.
 JFIRST(I) - COLUMN NUMBER OF FIRST CALCULATED GRID
 POINT IN ROW I.
 NFIXED - NUMBER OF POINTS IN ROW I THAT ARE NOT
 COMPUTED.
 XNPTS - NUMBER OF COMPUTED POINTS IN GRID.
 Q - VERTICAL RATE OF HEAT FLUX.
 OMEGA - ACCELERATION CONSTANT IN THE RELAXATION.
 (FIXED AT 1.5)

Table No. 4: Program Output

to surface temperatures, certain interior temperatures are needed to develop the mathematical model. For these reasons, a program was undertaken to establish operational temperatures for a ceramic coated piston and exhaust valve. Needed information included temperature data at known points for various power levels for uncoated parts and for parts with 0.040 inch, 0.070 inch and 0.100 inch coating of plasma sprayed yttrium stabilized zirconium oxide.

TEST FACILITIES

The engine selected for acquisition of temperature data was the same as that used for the previous performance data of ceramic coated parts. This was a cooperative fuel research (CFR) engine incorporating the low speed crankcase and the split cylinder head. The engine and the associated laboratory are shown in figure 12. An engine schematic is illustrated in figure 13.

Intake air was drawn through an ice tower to control humidity. It then passed through a flow control system consisting of a laminar flow element, a surge chamber and a throttle valve. By this method a constant humidity, pressure and temperature of air was available to the engine for all tests.

Fuel for all tests was commercial liquified petroleum gas (LPG).

Lubricating oil temperature was controllable by an electric heater located in the oil sump. Engine cooling was by the standard CFR boiling water jacket.

Engine power output was measured by an indicated mean effective pressure (IMEP) method. This technique incorporates a strain gauge pressure transducer located in the combustion chamber, an engine rotational position transducer on the crankshaft and a cycle indicator located on the camshaft. These three transducers provide the necessary data input to a PET 2001-8 computer for the solution of the following equation:

$$\text{IMEP} = \int pdv \quad (20)$$

The average of several of the above solutions provides an average

Figure 12: Engine Laboratory

Figure 13: Engine Schematic

value of the IMEP for any operational condition. This value is recorded as engine power level.

Those familiar with temperature measurement recognize the problems in establishing accurate data at point sources in ceramic substances. Such sources on the interior of metallic parts also offer a significant challenge. Finally, when one locates these points on a reciprocating piston (valve) of an operational engine, the full complexity of the situation becomes apparent.

The above problem can be subdivided into two parts: 1) what method should be used to measure each point temperature, and 2) how should the signal be transmitted from moving parts to the exterior of the engine?

Historically, thermocouples (including thin film deposited types), deposited thin film resistors, thermisters and Templugs have been successfully used for general temperature measurement.

Plasma sprayed surfaces are relatively porous which would greatly reduce the probability of successful application of thin film deposited type devices. Ceramic surfaces that are attached to a metal structure make the attachment and routing of leadwires nearly impossible.

In this project, the ceramic surface must be reduced from 0.100 inch thickness to zero in three stages by a surface grinding technique. Such a process would necessarily destroy any surface device and require the reinstallation and recalibration of a new one.

Templugs are a threaded metal insert that measure temperature by hardness change. These devices measure only the peak temperature and would not be compatible with a plasma sprayed surface.

Recognizing the problems with temperature measurement on a ceramic surface in the combustion chamber of a reciprocating I-C engine, it was decided that optical techniques offered the best hope of success.

It is known that all surfaces emit an infrared radiation as a direct function of surface temperature. Therefore, if this signal could be viewed and transmitted outside the engine, a method would have been found to instantaneously measure surface temperature without touching or affecting the surface.

The infrared signal transmission problem was solved by a system of water cooled probes that incorporated a glass fiber optics bundle. One bundle was designed so it could view both the top and surface of the piston and the lower surface of the exhaust valve. Both of these surfaces were within the chamber. A second bundle was used to view the exhaust valve tulip (manifold) surface. Details of these probes and associated hardware follows.

Figure 14 shows details of an actual fiber optics bundle and the water cooled probe into which it is assembled. This probe is shown in position on the engine in figure 15. Note that the probe fits into a deck spacer between the engine cylinder and cylinder head. This technique allows the probe to be moved in and out to view various radial positions and to be rotated 180° to alternately inspect the piston and the valve surface.

Figure 16 displays details of a second water cooled probe designed to view the exhaust valve tulip. Installation of this probe into the CFR cylinder head is seen in figure 17.

The optical signal from both of these probes is transmitted by flexible fiber optics to a detector that converts the I-R signal to an electric voltage. The electric signal is read as a temperature by an analyzer.

During the tests the PET 2001-8 computer served as the I-R temperature readout device, reading each probe temperature at a selected engine position. For the piston, the reading position was the top dead center (TDC) position on the exhaust-intake overlap event. The combustion chamber valve surface was read at this same cyclic position. The valve tulip was monitored with the valve closed at the BDC position at the end of the intake stroke.

SEMIADIABATIC PISTON

As stated previously, piston temperatures were required both on the combustion chamber and crankcase surfaces, as well as on selected points on the interior of the metallic structure. Instrumentation plans called for the piston combustion chamber surface to be measured

Figure 14: Fiber Optics
Combustion Chamber

Figure 15: Combustion Chamber
Probe Installation

Figure 16: Fiber Optics Exhaust Port

Figure 17: Exhaust Port
Probe Installation

by an infrared probe while all other temperatures used thermocouples.

The basic piston design adopted is seen in cross section in figure 18 and in assembly in figure 19. This is a three component piston consisting of a steel crown, a phenolic spacer and an aluminum skirt in assembly. The crown is fastened to the skirt by a series of screws.

The piston crown is a symmetrical design (to insure two direction heat flow) with access holes drilled for interior thermocouple insertion. These thermocouples were held in place by a ceramic cement. Other thermocouples are attached to the lower surface by peening. Figure 20 identifies the position of the eleven thermocouples used. Figure 21 shows the piston crown with thermocouples installed. Also shown, in position, is the phenolic insulator. Note that a series of holes have been designed into each side of the insulator. These holes provide a screw type connection between the fine wire (0.015 inch) iron constantan thermocouples and the stranded 30 gauge leadwire. Thirteen wires are routed through the piston skirt shown in figure 22 and 23; two of these wires served as redundant commons while the other eleven were signal wires for each of the eleven thermocouples.

THERMOCOUPLE WIRE ROUTING

Leadwire termination on the piston was by high temperature epoxy, as was the attachment to the connecting rod. Note in figure 24 that stress relief loops have been placed at the junction between the piston and connecting rod.

At the big end of the connecting rod another stress relief loop joined the span between the connecting rod and the swivel of a multibar support mechanism. This mechanism was designed to penetrate the crankcase at a sliding-rotating bearing and provide support for the thermocouple leadwires. An exterior view of this device is seen in figure 25. The base of the multibar mechanism is a pin joint attached to the engine baseplate. The thermocouple wires continue from this location through a selector switch to computer and digital readout.

The exhaust valve configuration without ceramic coating is shown

Figure 18: Piston Cross Section

Figure 24: Piston-Connecting Rod Assembly

Figure 25: Multilink Support Mechanism

in figure 26. As with the piston a 0.100 inch coating of yttrium stabilized zirconium oxide was applied by plasma spray. Coating thickness was reduced to 0.070, 0.040 and 0.000 inches for repeated tests. Controlled valve seat contact was established by hand grinding, lapping and fitting. Special gauges were fabricated to insure repeatability of valve seat contact. The valve grid network utilized in this test is defined by radial locations as viewed by the fiber optics probe and as portrayed in figure 27.

ENGINE ASSEMBLY

Figure 28 portrays the engine as assembled for final test. Note-worthy items are:

- (A) Engine rotational position transducers
- (B) Cycle position transducer
- (C) Multibar support mechanism
- (D) Deck spacer with fiber optics.

Engine test specifications follow in table 5:

Table 5

Bore	3.25 inch
Stroke	4.50 inch
Compression ratio	6.5 to 1
Cooling water temperature	210° F
Lubricating oil temperature	120° F
Ignition timing	10° BTDC
RPM	630
Fuel	Commercial liquified Petroleum gas

TEST PROCEDURE AND DATA

The data required for ceramic coating evaluation was as follows:

- 1) Metal ceramic interface temperature or thermocouple output for numbers 1, 2, 3, 4, & 9.
- 2) Ring belt temperature or thermocouple output for number 10 & 11.

Figure 26: Valve Configuration

Figure 27: Valve Grid Network

51

Figure 28: Engine Assembly

- 3) Crankcase surface temperature or thermocouple output for numbers 5, 6, 7, & 8.
- 4) Piston and valve combustion chamber surface or infrared output at various radial positions.
- 5) Valve tulip surface temperature at various positions.

The above data values were determined for ceramic coating thickness of 0.100, 0.070, 0.040, 0.000 inches at 5 power levels corresponding to 100%, 75%, 50%, 25% and motoring. This data is displayed in the top profiles of tables 6 & 7, respectively. Interpretation of tabulation has previously been outlined. Heat transfer and the calculated temperature and distribution is shown below the top profile. Maximum power for this version of the CFR engine corresponded to an indicated mean effective pressure of 40.5 psi. In each test, a fuel flow was established that produced this rated power. Fuel flow was incrementally reduced to produce the indicated steps of reduced power. Engine temperatures were allowed to stabilize before data was taken.

DATA ANALYSIS

The results of the preceding calculations are displayed in tables 8 and 9. Table 8 displays heat transfer information based on boundary conditions using infrared data as well as thermocouples. Table 9 is comparative data for the piston only, based on thermocouple data.

In both cases, the data shows the expected reduction in heat flow with increased coating thickness. The correlation between the sets of data, however, is not good. The great difference in heat flow for infrared and noninfrared calculations leads one to believe that the accuracy of the surface temperature measurement is poor.

ENDURANCE TEST

As previously stated, a part of this project was to establish the endurance behavior for zirconium oxide coated engine parts. Actually, the test described, herein, was the continuation of a 1000 hour en-

Table 6 (continued)
Valve Temperature Profiles

THE THERMAL CONDUCTIVITY FOR THE INSULATION IS 0.40000
THE THERMAL CONDUCTIVITY FOR THE METAL IS 33.00000
THE TOLERANCE FOR CHANGE IN AVG ELEMENT TEMP BETWEEN ITERATIONS IS 0.10000
THE TOLERANCE FOR MAXIMUM CHANGE IN TEMPERATURE IS 0.10000
NOTE THE UPPER LEFT HAND CORNER IS THE TOP CENTER OF THE PISTON OR VALVE.

durance test performed under an earlier grant.

The purpose of this test was to identify failure modes of zirconium oxide coatings in internal combustion engine combustion chambers. Three types of metal are commonly found in engines: aluminum, cast iron and steel. It was, therefore, desirable to test the behavior of all three materials with various coating thicknesses.

To satisfy the test criteria, a 1952 Chevrolet 216 cubic inch, 6 cylinder engine was selected. This particular engine was chosen since both cast iron and aluminum pistons are available. This engine was remanufactured and fitted with new oversize pistons, three, of which were cast iron and three were aluminum. Prior to assembly, the pistons were coated with a nominal 0.03, 0.06 and 0.10 inch coating of yttrium stabilized zirconium oxide. The piston tops were machined to reduce thicknesses so that all pistons would have the same height after coating. The valves and combustion chamber walls were also coated with ceramic to the above thicknesses. Figures 29 and 30 portray typical preassembly component details.

The engine was assembled and operated on a simulated driving cycle for a first 1000 hours. This driving cycle consisted of 23 hours plus 55 minutes at 2000 rpm at 30% of maximum power, followed by 5 minutes at full power also at 2000 rpm. No operational data, except time, was recorded.

Following the first 1000 hours, the engine was disassembled and inspected. No significant coating degradation was found, except on the perimeter of the intake valves; here, most of the ceramic had separated.

The second 1000 hours test proceeded after an engine overhaul that included new piston rings and bearings.

The second test was conducted with the same simulated driving cycle. Forty hours into the second 1000 hour test, a generator failure resulted in the fan belt failure. This, in turn, caused high engine temperature. A coincidental failure of the safety switch allowed the engine to run to seizure. Following this problem, the engine was again overhauled and placed into service with all of the original ceram-

Figure 29: Endurance Engine Cylinder Head

Figure 30: Endurance Engine Piston

ic surfaces.

After 2000 hours of exposure, the engine was disassembled and inspected. As before, no significant problems were observed with the coating. The piston surfaces had some heat cracks and some feathering on the perimeter; no additional separations had occurred, however, since the first 1000 hours.

Figures 31-36 portray typical surfaces after 2000 hours of operation. Note that some surfaces seem abraded and, in some cases, this condition goes to the base metal. This abrasion is the result of glass bead blasting that not only removed carbon deposits, but also, the ceramic coating. The coating was secure and in place prior to blasting.

SUMMARY AND CONCLUSIONS

The preceding document outlines details of a study of heat transfer, temperature profiles and endurance for ceramic coated internal combustion engine parts. Such parts offer significant promise in the advancement of engine technology.

The first objective of the study was to create a mathematical model that could predict heat transfer and temperatures within coated pistons and valves. This model was developed, and is presented, in computer card format. With this model, a design engineer should be able to optimize such parts for any engine application.

The second objective was to measure operational temperatures of a piston and a valve with various thicknesses of coating at various power levels. To do this, two rather novel techniques were used. Thermocouples were installed in moving crankcase piston surfaces and the signal was routed by hard wire techniques out of the crankcase. This procedure was quite successful and produced excellent results.

The second technique incorporated fiber optic probes to measure combustion chamber surface temperatures using infrared detectors. This procedure produced poor results in spite of extensive calibration efforts. It is believed that this method can be made to work, and with additional development will be an extremely valuable tool for

Figure 31:
Cylinder Head Surfaces

Figure 32:
Cylinder Head Surfaces

Figure 33: Valve Surfaces

Figure 34: Valve Surfaces

Figure 35: Piston Surfaces

Figure 36: Piston Surfaces

engine research.

It is recommended that additional efforts be undertaken to perfect the fiber optics, infrared technique.

The third objective was the continuation of an earlier 1000 hour endurance test of ceramic coated engine parts. This final test added a second 1000 hour of time to the existing engine. This effort proved without doubt that ceramic coated parts can endure the torturous environment of I-C engines without significant degradation.

ACKNOWLEDGEMENT

The authors wish to express their appreciation to the U.S. Army research office for the opportunity to examine this most important area of engine technology.

They also wish to express their gratitude to the dedicated staff that made the project a success.

Thermophysical Properties of a Coating

INTRODUCTION

Four duplicate samples of a zirconia coating on a steel sample were furnished by Dr. Murray of Oklahoma State University for thermal conductivity determinations. The samples were nominally 0.5 inch diameter and 0.1 inch thick with the steel comprising a little over one-half of the thickness. The basic approach to be used to determine the thermal conductivity "k" was to measure the thermal diffusivity, " α ", specific heat " C_p " and density "d" since $k = \alpha C_p d$. The bulk densities were determined from mass and geometry measurements, the specific heat was measured using a differential scanning calorimeter, and the thermal diffusivity " α " was measured using the laser flash method. This technique for obtaining thermal conductivity is widely used and has the advantages of simple small sample size, and the elimination of the heat flux and temperature gradient measurements. These later measurements, combined with extraneous heat flows, are the primary reasons why direct conductivity measurements are difficult and often yield poor results.

The Perkin-Elmer DSC II differential scanning calorimeter is used for routine determinations of specific heat up to 700° C. The differential heat required to heat the sample and a standard sapphire specimen is measured. From the mass of the sample and the sapphire and the known specific heat of sapphire, the specific heat of the unknown can be calculated. A continuous recording of microcalories versus temperature is obtained during the experiment.

The flash method in which the front face of a small disc-shaped sample is subjected to a short laser burst and the resulting rear face temperature rise is recorded, is used in over 80% of the present thermal diffusivity measurements throughout the world. A highly developed apparatus exists at TPRL and we have been involved in an extensive program to evaluate the technique and broaden its uses. The apparatus consists of a Korad K2 laser, a high vacuum system including a bell jar with windows for viewing the sample, a tantalum tube heater surrounding a sample holding assembly, a spring-loaded thermocouple, appropriate biasing circuits, amplifiers, A-D converters, crystal clocks, and a minicomputer-based digital data acquisition system capable of accurately taking data in the 40 microsecond and longer time domain. The computer controls the experiment, collects the data, calculates the results, and compared the raw data with the theoretical model. A typical visual display

is shown in Figure 1. The raw data are given in Table 1 and the computations are given in Table 2. The vertical axis of Figure 1 is non-dimensional temperature rise (the temperature rise at anytime divided by the maximum rise). The horizontal axis is non-dimensional time (the time from the initiation of the laser pulse divided by the time to reach one-half of the maximum temperature rise). The solid curve represents the theoretical model and the points are the actual data. Note the close agreement between the experimental data and the mathematical model (Figure 1). The calculated results given in Table 2 were obtained from the computer output of Table 1. The column headed "ALPHA" are the diffusivity values ($\text{cm}^2 \text{ sec}^{-1}$) calculated assuming no finite pulse effect at various percent rises (PER). The column marked "VALUE" is the emf output corresponding to the percent rise and "TIME" represents the time in seconds from the initiation of the pulse until the rear face temperature rise reached the indicated percent value. The resulting values of α range from 0.00309 to 0.00321 between 10 and 80% of the temperature rise (Table 2) and the best value is $0.00320 \text{ cm}^2 \text{ sec}^{-1}$.

A special technique has been developed to measure the thermal diffusivity of one layer in intimate contact with a second layer. The half-time for the composite is measured and the rise curve is compared to the theoretical model in the usual fashion. In order to use this method, it is necessary to know the thicknesses, specific heats and densities of the two layers and the diffusivity of the second layer. Thus these properties were measured for the steel sample using a blank furnished by Dr. Murray. However, the rise curves for the composite samples did not follow the theoretical model, showing that interfacial contact resistance was present. A typical result is shown in Figure 2. Note the differences between the theoretical and experimental rise curves. Since the coatings were reasonably thick and could be removed from the substrate, the diffusivity of the free-standing coating was measured directly. In fact the visual display of Figure 1 and the data of Tables 1 and 2 are from the free-standing coating at room temperature.

RESULTS

The thermal diffusivity results for the coating and for the steel blank are given in Table 3. The diffusivity results for the coating are plotted in Figure 3. It was noted that the diffusivity values were unstable with time between 250 and 500° C and consequently measurements were made during the cooling cycle. These values were significantly less than those attained during initial heating.

The specific heat results for the coating and for the steel are given in Table 4 and plotted in Figure 4. A large peak was noted in the specific heat of the coating during the initial heating cycle (Figure 4). Thus the sample was rerun and the peak disappeared. This behavior occurred over the same temperature range in which the diffusivity values were unstable (Figure 3) and the two phenomena are undoubtedly related.

Thermal conductivity values are calculated in Table 5 and plotted in Figure 5. No calculations were made between 300 and 500° C for the initial heating data as the specific heat and diffusivity values are certainly time-temperature dependent. However the cooling curve data (diffusivity) and second run data (specific heat) are representative of this material after temperature cycling to 500° C (1000° F).

With the knowledge of the thermal properties of both layers, it is possible to calculate the contact conductance for the two-layer case. These values ranged from 2.4 to 4.2 W cm⁻² K⁻¹ at room temperature for the three samples which were not sectioned.

The conductance values at higher temperatures or the changes caused by temperature cycling were not determined, although it would be possible to do so.

DISCUSSION

The changes in specific heat and thermal diffusivity (and consequently conductivity) noted during initial heating are undoubtedly due to the removal of a contaminant. We have often observed similar phenomena on other samples of materials which were significantly less than theoretical density. The sensitivity and accuracy of advanced computer-aided instrumentation and methods makes such changes readily discernable. However, unless one is interested in initial heating conditions, one should use the values generated during the cooling or second run curves.
